Abstract: The experimental and computational data on rhodium binary alloys is sparse despite its importance in numerous applications, especially as an alloying agent in catalytic materials. Half of the Rh-transition metal systems (14 out of 28) are reported to be phase separating or are lacking experimental data. Comprehensive high-throughput first-principles calculations predict stable ordered structures in 9 of those 14 binary systems. They also predict a few unreported compounds in the known compound-forming systems. These results indicate the need for an extensive revision of our current understanding of Rh alloys through a combination of theoretical predictions and experimental validations.

1. Introduction

Like other elements in the platinum group metals (PGMs) (ruthenium, osmium, iridium, palladium, and platinum), rhodium has a high catalytic potential for a variety of chemical reactions.1,2 It is used as an alloying agent with platinum and palladium to improve catalytic activity and selectivity, or for coating to improve hardness and corrosion resistance in applications requiring high chemical and mechanical durability. Despite the wealth of existing and potential applications, the investigations of rhodium binary systems are less common. Theoretical studies of the Co–Rh, Mn–Rh, and Fe–Rh systems,25–29 motivated by their peculiar magnetic properties, did not address phase stability of possible compounds. A study of Rh bimetallic intermetallic catalysts led to preliminary studies of a few PGM alloys and surface alloys30–34 that clarified the need to evaluate the stability of new potential alloy catalysts. However, investigations of rhodium binary systems are less common. alloys with Ag, Au, Cu, and Pd\textsuperscript{30} confirmed the experimentally observed phase separation in those systems. An early indication that the existing experimental data may be incomplete appeared in ref 31, where first-principles local-density approximation (LDA) and cluster expansion (CE) calculations found unobserved compounds in the Rh–Pt system. Later studies, using similar methods, confirmed this finding\textsuperscript{32–35} and showed that Cd–Rh, Ru–Rh, Ru–Te,\textsuperscript{32} and Ir–Rh\textsuperscript{33,34} are also compound forming at low temperatures. The importance of re-examining the Rh binary systems is underscored by the recent finding that certain surface alloys of ReRh and CuRh might be better electrocatalysts than pure PGMs for hydrogen-evolution reactions;\textsuperscript{21,22} these two binary systems were believed to be phase separating but are predicted in this work to be compound forming.

2. Predictions via a High-Throughput Approach

High-throughput (HT) calculations of material properties based on DFT have acquired an increasing role in recent years as an important tool for rational material development.\textsuperscript{32,36–40} They can be used to explore the phase stability landscape of binary alloys by calculating the formation enthalpies of a large number of structures, identifying the minima at various component concentrations. A minimum-free-energy convex hull is constructed from these minimum-energy structures. These calculations give insight into general trends of material properties, indicating the possible existence of hitherto unobserved compounds and their characteristics. The results reported in this contribution demonstrate the effectiveness of this approach in studying binary metallic systems where experimental data are scarce and difficult to obtain.

The HT approach finds new stable structures both in systems known to order and those thought to be phase separating. Of the 14 rhodium binary intermetallic systems that are either reported as phase separating or essentially unreported in the literature,\textsuperscript{41,42} we show that nine actually exhibit ordering tendencies, forming stable compounds at low temperatures (Figure 1). Specifically, we find new structures in four binary systems not previously studied: Re–Rh, Os–Rh, Cu–Rh, and Zn–Rh, and a few previously unreported stable structures in the five systems already predicted to be ordering, as discussed above (Rh–Pt, Ir–Rh, Cd–Rh, Ru–Rh, and Rh–Te). In addition to these nine systems, we also predict new stable structures in two of the three binary systems known to be compound forming, Mn–Rh and Fe–Rh. In the third system, Hg–Rh, the HT method confirms a single stable compound Hg\(_2\)Rh, of prototype HgPt.

3. Methods

The calculations were performed using the high-throughput framework AFLOW\textsuperscript{32,42} based on \textit{ab initio} calculations of the energies by the VASP software.\textsuperscript{43} We used projector augmented waves (PAW) pseudopotentials\textsuperscript{44} and the exchange-correlation functionals parametrized by Perdew, Burke, and Ernzerhof\textsuperscript{45} (PBE) for the generalized gradient approximation (GGA). The energies were calculated at zero temperature and pressure, with spin polarization and without zero-point motion or lattice vibrations (zero-point motion is negligible because we do not consider light elements). All crystal structures were fully relaxed (cell volume and shape and the basis atom coordinates inside the cell). Numerical convergence to about 1 meV/atom was ensured by a high energy cutoff (30% higher than the highest-energy cutoff for the pseudopotentials of the components) and dense 6000 k-point Monkhorst–Pack meshes. Since the calculations are performed at zero temperature and pressure and the volume is fully relaxed, the calculated energies coincide with the enthalpies, and their accuracy is the same. For each system, the energies of 200 crystal structures were calculated. In addition to the 176 configurations described in ref 32 these included all the symmetrically distinct hcp-, bcc-, fcc-based superstructures\textsuperscript{46,47} with up to four atoms per cell, and the prototypes A5, A6, A7, A8, A9, A11, B20, C36, D519, Al\(_2\)Zr, Al\(_2\)Zr\(_2\), CdTi, CuPt\(_2\), CuTi, GaH\(_6\), GaPt\(_3\), GaTi, HgPt, InTi, LiB\(_3\)Si\(_2\), \(\text{NiTi}_2\), SeTl, and V\(_4\)Zn\(_5\). The prototypes were considered because they are common or related to Rh alloys.\textsuperscript{48} This protocol gives reasonable results. In ref 32 it was shown that the probability of reproducing the correct ground state, if well-defined and not ambiguous, is \(\eta^*\approx 96.7\%\) ("reliability of the method", eq 3). There is no guarantee that the true ground states of a system will be found among the common experimentally observed structures or among small unit-cell derivative structures. However, even if it is impossible to rule out the existence of an unexpected ground state, this protocol (searching many enumerated derivative structures and exhaustively exploring experimentally reported structures) is expected to give a reasonable balance between high-throughput speed and scientific accuracy to determine miscibility (or lack thereof) in Rh alloys.

Table 1. Compounds Observed in Experiments or Predicted by ab initio Calculations in Rh Binary Alloys (Structure Prototype or Space Group Number in Parentheses) (49)

 ordered structures are found in the RhZn system. They are RhZn (prototype B2), RhZn₂ (prototype ZrSi₂), and RhZn₃ (prototype D₀₁₃₂). Three ordered structures with prototypes ZrSi₂, B₁₉, and D₀₁₃₂ are also found in the Re–Rh system. These same structures were found in the Rh–Tc system and are reproduced in this study. The Rh–Ru results follow the same ground states of ref 32.

In the Pt–Rh system, previous studies using the CE method and LDA first-principles calculations defined a convex hull [20] for PtRh4. Two additional structures, D₁₃₂ for PtRh and C₄₉ for PtRh₂, were found in later LDA calculations. Our PAW–PBE calculations [32] confirm the appearance of the

4. Results and Discussion

The results are summarized in Table 1. In the first column, the 17 alloying metals are ordered according to their Mendeleev number (or Pettifor’s chemical scale). The next three columns indicate whether the corresponding binary system is phase separating or compound forming, according to the experimental data and to ab initio calculations reported here and in previous studies. Ordered in this way, the experimentally reported compound-forming systems are scattered: Two, Mn–Rh and Fe–Rh, near the top of the table and one, Hg–Rh, near the bottom. (Ordering in Rh–Zn and Rh–Cd is suspected but unconfirmed experimentally.) Our calculations find stable structures in all the systems nearby these three in the list. The remaining phase-separating systems form a small cluster of three, Pd–Rh, Au–Rh, and Ag–Rh, and two more systems, Co–Rh and Ni–Rh, slightly above it. This grouping of the predicted phase-separating systems essentially complements the trend indicated by the Pettifor chemical scale. The ratio of phase-

in the [311] direction (space group is the same single structure reported in the literature. CH40 is the short name for FCC\[311\] as in refs 31 and 32.

FCC\[311\] and two D0_{32} structures but predict that C49 and D1_{a} are metastable, lying just above the convex hull.

An extensive CE search of \(\sim 3 \times 10^{6}\) configurations in the Ir−Rh system, based on 73 LDA structure calculations, found a few ground-state structures with large unit cells, of about 20 atoms per cell. Our current search of 200 PAW−PBE calculations found a very similar convex hull defined by a few fcc superstructures with much smaller cells. The lowest structure, at \(-21\) meV/atom, has four atoms per cell. It is an A2B2 stacking in the [311] direction (space group C2/m, #12). It is designated W2 in ref 51 and FCC\[311\] in ref 32. The additional structures are the MoPt2 prototype, with three atoms per unit cell, for IrRh2 and Ir2 Rh, and four atoms per unit cell FCC\[113\] (space group C2/m, #12) for IrRh3 and IrRh4.

In the Cd−Rh system, a previous LDA study found the ordered structures D0_{34} for CdRh and C37 for Cd_{2}Rh. Our more extensive PAW−PBE search finds a convex hull defined by a single structure Cd_{2}Rh with prototype Hg_{2}Pt. The two previous structures lie a few meV above the convex hull. This is the same single structure reported in the Hg−Rh system. It is interesting to note that the experimentally observed Hg_{2}Rh structure defines a much shallower convex hull than the unobserved Cd_{2}Rh structure (see Figures 2,3).

In agreement with the experimental data, we find stable compounds in the Hg−Rh, Fe−Rh, and Mn−Rh systems. The convex hulls of these systems are shown in Figure 3. As mentioned above, the existence of a single compound in the Hg−Rh is reproduced with the reported prototype Hg_{2}Pt. The reported B2 compound in the Mn−Rh and Fe−Rh systems is also reproduced. However, additional stable structures are found in these two systems (Fe_{2}Rh-BCC\[300\], Fe_{2}Rh-C11_{b}, Fe_{2}Rh-D0_{31}, Mn_{2}Rh-D0_{11}, and Mn_{2}Rh−CuPt_{4}). Similar to the B2 compounds, the appearance of these ordered structures is accompanied by large magnetic moments which contribute to their stability (Table 1). Without magnetic degrees of freedom, the calculated energies of these ordered structures would have been higher. The reported Mn_{2}Rh compound is found to lie above the convex hull in our calculations and is therefore unstable at low temperatures (the experimental data are available at temperatures above 400 °C). At this composition, the lowest-energy structure with fcc superlattice is 27 meV/atom above the Mn−Mn_{2}Rh(B2) tie line. At high temperatures, it is perhaps stabilized by vibrational entropy, which is of the order of 0.1 to 0.2 k_{B}/atom, comparable to the typical values of configurational entropy differences in binary alloys (\(\leq 0.693\) k_{B}/atom). Configurational entropy is not expected to play a major role in the phase stability at the fixed stoichiometry of Mn_{2}Rh, because of the high energy cost of substitutional and interstitial defects. Vibrational stabilization is common, e.g. in ref 53 the vibrational entropy difference is shown to stabilize the \(\theta−Al_{2}Cu\) (C16) phase over the competing \(Al_{2}Cu−\theta^{′}\) phase (distortion of \(\theta^{′}−C1\)), which has the lowest energy and is, therefore, stable at low temperatures.

The crystal structure of rhodium is fcc. In 7 of its 14 binary systems reported as phase separating, the alloying element shares the fcc structure. In the other seven, the alloying element’s structure is hcp. As discussed above, it was previously predicted that two of these fcc elements (Pt and Ir) and three of the hcp elements (Cd, Ru, and Tc) form stable ordered structures when mixed with Rh. The study reported in this contribution complements this picture and shows that Rh forms ordered structures with three of these fcc elements and six of the hcp elements. Its phase-separating bimetallic systems are only those with the fcc elements Ag and Au and its immediate neighbors in the periodic table Co (hcp) and Ni and Pd (both fcc).

5. Conclusion

The bulk phase behavior of alloys determines to a large extent the surface and small particle properties that dominate catalytic processes. A detailed understanding of Rh alloys is crucial for

a better realization of its potential as a catalytic agent in currently known processes and in developing new ones. This is demonstrated by the recent finding that certain surface alloys of ReRh and CuRh might be better electrocatalysts than pure PGMs for hydrogen evolution reactions.21,22 These two binary systems were believed to be phase separating but are predicted here to be compound forming.

A recent study of the Cu–Pt–Rh ternary system was also motivated by the search for better catalysts.54 It presents a calculation of the ternary formation energy diagram based on the assumption that the binary Cu–Rh system is phase separating. This ternary diagram would be considerably modified by our prediction of compound formation in the Cu–Rh system. Similar modification of other relevant ternary systems would ensue from all the predicted compound-forming systems in this study. As remarked in ref 54, the theoretical prediction of phase ordering and stability in these systems should be the starting point for designing desirable alloy catalysts.

The picture of Rh alloys that emerges from this study is very different from that depicted by current experimental data. Instead of many phase-separating systems, we predict that all but just five form ordered structures. It should be emphasized that we consider the alloys in thermodynamical equilibrium which can be difficult to reach at low temperatures due to slow kinetics. At higher temperatures, configurational disorder and vibrational entropic promotion might destabilize the predicted compounds. Experimental validation is the ultimate proof of compound existence. The theoretical predictions presented here complement the woefully incomplete experimental picture and serve as a guide for future experimental and theoretical studies of these important catalytic materials.
